**Abstract**

Ural-Alaskan- (or Alaskan-) type complexes correspond to a particular class of ultramafic intrusions that attract particular attention due to their deep mantle origin and their platinum-group element (PGE) mineralization. When defined as massifs of dunite-clinopyroxenite, only forty-six complexes are reported in the literature. These large-scale dunite pipe-like structures are rarely isolated and they even can appear in clusters. To better understand genesis of these relatively young (< 460 Ma) complexes, a worldwide compilation has been built, and three categories have been defined: single circular or elliptical bodies, twin bodies with similar shapes, and dismembered dunite bodies. PGE enrichment in Alaskan-type complexes is highest for the second category, where twin bodies are interpreted as horizontal sections of Y-shaped dunite pipes. To constrain mechanical properties of the lithosphere allowing emplacement of the Alaskan-type complexes, the forceful diapiric ascent hypothesis is investigated through numerical thermo-mechanical models. One hundred high resolution experiments accounting for realistic phase changes and softening mechanisms have been performed. The experiments show that with no rheological softening of the host rock and in case of a relatively weak ductile lower crust, the uprising magma tends to spread laterally without reaching the surface. To account for the forceful ascent of deep magmas, it is hence necessary to assume a strong lower crust rheology and strong local softening mechanisms. Besides reproducing the clustered distribution of the weakness zones representing magma pathways, these latter experiments reproduce large-scale pipe-like (cylindrical) structures, Y-shaped and funnel-shaped bodies, and laterally-shifted structures. Interestingly, zones of highest strain rates are located at the bottom parts of the inclined edges of Y-shaped and funnel-shaped bodies. The restricted age range of Alaskan-type complexes (< 460 Ma) would mean that prior to this time, the lower crust was less resistant due to the hotter geotherm, prohibiting the possibility of “Alaskan-type magmatism”.

**Keywords**: Ural-Alaskan complexes; Dunite core geometry; Magma ascent mechanisms; Platinum-group elements; Numerical modelling; Rheology; Softening
1. Introduction

Alaskan-type (or Ural-Alaskan-type) complexes represent a group of ultramafic bodies where orthopyroxene is generally absent, and can thus be described as dunite-clinopyroxenite massifs. They have been originally defined as intrusions of olivine-rich lithologies (considered as mantle-derived material) with a concentrically zoned distribution, evolving from a dunite core to a clinopyroxenite rim, with gabbros or diorites at the margins (Taylor, 1967). The size of Alaskan-type complexes ranges from a few to hundreds of km², with one exception, the Guli massif, reaching 2000 km². In map view, they present circular or elliptical geometries, and can appear as isolated bodies or accompanied by a twin body of similar size, each of them being separated by a few kilometres. At a larger scale (hundreds of kilometres), several Alaskan-type bodies can be gathered in clusters, like in the Urals or in south-eastern Alaska (Figure 1). Although ultramafic rocks of various typologies can be found in many places on Earth, Alaskan-type complexes are very scarce since only 46 complexes can really fit the above definition of a dunite core surrounded by a clinopyroxenite rim (Table 1). Twelve other ultramafic bodies were classified in the past as Alaskan-type complexes but they do not include a dunite core, and hence they are not listed in Table 1 (e.g. Turn Mountain, Salt Chuck and Sukkwan Island ultramafic bodies in SE Alaska, Himmelberg and Loney, 1995). There is also no evidence for a dunite core in the so-called Alaskan-type complexes of Gnat Lake or Menard Creek ultramafic bodies in British Columbia (Nixon et al., 1997). Similarly, although Pettigrew and Hattori (2006) suggested that the Neo-Archean ultramafic intrusions in the Quetico subprovince, Canada, correspond to Alaskan-type complexes, it appears that their cores are made of wehrlite (less than 90% of olivine) and not of dunite. Nevertheless, even if the listed number of Alaskan-type complexes depends on their definition and on the interpretation of geological maps, their scarcity is noteworthy evident. Besides their scarcity, dunite-clinopyroxenite massifs show another intriguing feature, dealing with their ages: Alaskan-type complexes were emplaced during a small part of the Earth history, from 460 to 20 Ma.
Ultramafic bodies and Alaskan-type complexes in particular, have been studied for a long time because of their associated mineralization in platinum-group elements (PGE) (Johan, 2002). Platinum-Group Elements, which refer to six metals (osmium, iridium, ruthenium, rhodium, platinum and palladium), have become essential to modern industry and are now classified as "strategic" metals. Among these elements, two of them, iridium and platinum, are particularly present in Alaskan-type bodies, and it appears that the price of these two metals has been continuously increasing for the last decade. However, the number of exploited PGE ore deposits is largely limited to South Africa (Bushveld complex) and Russia (Noril'sk intrusion). In addition, the principal source of PGE in Alaskan-type complexes is placer deposit and not primary mineralization. This partly explains that there are only few studies dedicated to the emplacement mechanisms of Alaskan-type complexes which could help understand the conditions of PGE mineralization.

Platinum “nuggets” have been discovered and exploited within placers spatially associated with Alaskan-type bodies (e.g. Slansky et al., 1991; Tolstykh et al., 2000; Malitch et al., 2002; Barkov et al., 2005). Placers remain an important source for PGE production in Russia, after the Ni-Cu sulfides ores of Noril’sk-type intrusions (Johan, 2002; Malitch and Thalhammer, 2002). According to Thakurta et al. (2008) who studied the Alaskan-type Duke Island complex, southeastern Alaska, “the potential for the occurrence of world-class Cu-Ni-PGE sulphide deposits in Alaskan-type complexes should not be overlooked”. Although some authors consider the absence of sulphides as representative of Alaskan-type bodies (e.g. Johan, 2002), this feature is not retained in our definition (a dunite core surrounded by clinopyroxenites).

Another recent study (Nazimova et al., 2011) emphasized on the important platinum mineralization of the Galmoenan massif, Kamchatka, possibly defining, in addition to its well-known placer deposits, an economic, medium-size platinum deposit of primary type. Two hundred kilometres southwest of the Galmoenan complex, numerous platinum “nuggets” were also found in placers from the Pustaya River, which crosses the Koryak-Kamchatka platinum belt related to eroded Alaskan-type intrusions (Tolstykh et al., 2000). It must be
stressed that placers around Alaskan-type bodies are not the sole type of PGE mineralization. Indeed, several examples have shown that primary type mineralization, where PGE are associated with chromitite lenses within dunites, have been exploited in the past (e.g. Nizhny Tagil, Augé et al., 2005), but their contribution remains historically very low compared to placer production. However, chromite-bearing dunites within restricted parts of the dunite cores appear to represent a potential economic target (e.g. Galmoenan, Nazimova et al., 2011).

Often associated with the location of ancient subduction zones (Urals, Alaska, British Columbia, Kamchatka, Colombia), Alaskan-type complexes can also form in intracontinental settings (Siberia, Ethiopia, Far East Russia). Several mechanisms have been invoked to explain the ascent and emplacement of mantle-derived magmas at the Earth’s surface. Melting from mantle plume heads or from subduction settings have both been proposed. Although Alaskan-type complexes are not necessarily linked to subduction, they are still considered by some researchers as geological imprints of past subduction zones (e.g. Su et al., 2012). On the contrary, Sutherland (1998) suggested a plume model where magmatic diapirs derived from the plume head rise in zones of increasing tensional stress, creating “tube-like” intrusions (see also Burg et al., 1998; Pirajno et al., 2008). Studying ascent mechanisms of ultramafic bodies, Gerya and Burg (2007) and Burg et al. (2009) found that large-scale geodynamic processes are not necessarily required, and that local rheological properties could lead to “translithospheric diapirism”, a mechanism with which mantle-derived material could quickly rise up through the lithospheric mantle and the crust. In particular, a cold elastoplastic crust would facilitate the upward propagation through the crust. This process was initially suggested by Bodinier et al. (2002), who analysed microstructural, geochemical and mineralogical data from dunite and pyroxenites of the Kondyor complex. The authors concluded from previous gravimetric data and tectonic reconstructions that the massif represents “an apex of a dense ultramafic cylinder rooted down to, at least, 10 km depth”. Magma at the origin of the Kondyor dunite would have accumulated at the base of the lithospheric mantle, triggering a forcefully ascent of a solid-state dunite diapir. Here and
in the following, the “solid-state” ascent refers to the rheological behaviour of mantle-derived material, which corresponds to partially molten peridotite with a low density but a high effective viscosity.

The present study consists in looking for appropriate rheological conditions allowing simulations of magmatic processes at the origin of Alaskan-type complexes (fast ascent through the entire lithosphere, particular geometries at the surface, clustering process), through lithospheric-scale thermo-mechanical models that account for the properties of the involved magma. Realistic rheological laws for the crust and the lithosphere (see Supplementary material), as well as realistic phase changes, have been included in the thermo-mechanical numerical model. In particular, our numerical results focus on spatial distribution and geometries of the weakness zones that are created by the ascent of a deep and hot mafic magma.

2. Alaskan-type complexes: general description and classification

Alaskan-type complexes are defined by the following successive events: first a dunite core is emplaced; second, melt-rock reactions develop successively rims of wehrlite, followed by clinopyroxenites ± hornblende and then monzonite-gabbro (i.e. absence of orthopyroxene); the contacts between ultramafic and surrounding gabbroic rocks are sharp; the chemical composition of olivine in dunites is highly magnesian; chromite is a phase occurring exclusively in dunite, where it is ubiquitous and locally forms concentration occurring as schlieren or pseudo-layers enriched in PGE (see Johan, 2002 for a detailed review). Ultramafic and mafic rocks contain significant proportions of hydrated minerals (amphibole, phlogopite) and hydrated bodies (ultramafic-mafic pegmatoids). Additional common features to Alaskan-type complexes were later suggested, like the specific concentration and distribution of rare-earth elements (REE) in ultramafic and gabbroic rocks, or the relative absence of sulphides (see Johan, 2002). In the following, we present a distinct classification, based on pure geometrical considerations.

2.1 Surface expression
When geological maps of Alaskan-type complexes are examined, three distinct classes based on surface geometries can be defined, regardless of the geodynamic setting (Figure 2). The first category includes circular or elliptical surface expression of dunite and clinopyroxenite rims with an external diameter of several kilometres (Figure 2a). For some cases, more elongated shapes are observed (e.g. Yubdo, Gaositai, Nizhny Tagil, Wrede Creek, Figure 2c). The second category corresponds to twin bodies (similar shape and size), showing dunite cores of several kilometres in size separated by a few kilometres, each of them being surrounded by clinopyroxenites (e.g. Galmoenan, Goodnews Bay and Duke Island in Figure 2b; Kachkanar, Owendale and Condoto in Figure 2d). The third category includes disconnected dunite blocks of different sizes (e.g. Lunar Creek and Uktus, Figure 2d). All the other Alaskan-type complexes not shown in Figure 2 but listed in Table 1 can be classified in one of the three categories. For example, geological maps of the Turnagain, Red Bluff or Kane Peak ultramafic bodies (Himmelberg and Loney, 1995; Scheel et al., 2009) clearly indicate that they belong to the first category of Alaskan-type complexes. In British Columbia, the Polaris complex belongs to the second category since it comprises two main dunite cores separated by wehrlite and clinopyroxenite (Nixon et al., 1997). Third column of Table 1 indicates which category the Alaskan-type complex belongs to, with the number of dunite cores (one, two or several), when available.

2.2 Vertical models

As mentioned above, gravity measurements around the Kondyor massif led Efimov and Tavlin (1978) to suggest that ultramafic rocks extend as a cylindrical pipe down to a depth of at least 10 km. Interpretations of geological data at Union Bay, southeastern Alaska, by Ruckmick and Noble (1959) and Himmelberg and Loney (1995) suggest that ultramafic rocks delineate an almost vertical pipe with slightly decreasing diameter with depth (funnel-shaped pipe). Again, based on geological observations, van der Poel and Hinderman (2000) described the two twin bodies of the Goodnews Bay complex as vertical pipes widening out at the surface. Recently, the geometric model of the Duke Island complex proposed by Thakurta et al. (2008), which was derived from a previous model by Butler et al. (2001),
illustrates a three-branches structure, two of which including dunite pipes surrounded by clinopyroxenites, joining at depth and forming a common “trunk”. To summarize, vertical structure of Alaskan-type complexes would correspond to magmatic conduits (pipes) which could have pierced the mantle lithosphere and the crust through a diapirism mechanism (Bodinier et al., 2002; Gerya and Burg, 2007; Burg et al., 2009).

2.3 Clusters

Clustering of Alaskan-type complexes (Figure 1b) can be quantified by the averaged distance between nearest neighbours, which is around 60 km for the Urals, and around 30 km for south-eastern Alaska. For both cases, the role of past or present subduction zones has been invoked (Murray, 1972). Actually, there is no reason to get same values since volcanism related to subduction seems to be randomly distributed (de Brémond d’Ars et al., 1995). According to these authors, spatial distribution of subduction-related volcanoes would be representative of melting conditions and deep magmatic activity, such as recurrent magmatic pulses.

Clustering of Alaskan-type complexes is not necessarily linear (like in the Urals, Figure 1) and several neighbouring bodies seem to have been emplaced in a single event (see in Table 1 the ages of Alaskan-type complexes in the Urals, in Kamchatka, and in SE Alaska). Simultaneous emplacement of such deep magmatic bodies probably requires a particular thermo-mechanical event affecting the bulk crust over several hundreds of km.

Uprising of mantle-derived material through the lithosphere requires the development of weak crustal zones. The clustering phenomenon (of weak zones) might be analogous to the faulting spatial periodicity problem. Fracturing and faulting spatial periodicity has been extensively studied in the past decades (e.g. Ouillon et al., 1996). These authors concluded that faulting spatial periodicity is mainly controlled by rheological layering of the crust and not by the complex rupture process. Similarly, it is the rheology of the lower crust which appears to control folding of the lithosphere (Gerbault et al., 1999). In the following sections, the clustering of Alaskan-type complexes is investigated through distinct possible crustal rheologies.
3. Physical properties of ultramafic rocks and magmas

Physical properties of olivine-rich ultramafic rocks (density, thermal properties, and rheology) have been studied by several teams in the past (Chopra and Paterson, 1981, 1984; Chopra, 1997; Mei and Kohlstedt, 2000a, 2000b; Suzuki and Ohtani, 2003; Gibert et al., 2005; Wang, 2010; Keefner et al., 2011). Recently obtained data on clinopyroxene crystals from the Konder and Inagli massifs have shown a close composition and a similar configuration of REE patterns to those obtained with samples from the Alaskan-type Kytlym and Nizhni Tagil massifs (Simonov et al., 2011). The authors concluded that dunites of the Konder and Inagli massifs were produced by water-rich (up to 0.6%) magmas at temperatures of 1300-1460°C. This is in accordance with the amount of hydrated minerals (amphibole, phlogopite) and hydrated bodies (ultramafic-mafic pegmatoids) observed in such Alaskan-type complexes.

It is well-known that the presence of water strongly modifies rheological properties, and such hydrated magmas at high temperature may indeed undergo unexpected flow regimes. The presence of water in olivine rich magmas also induces a decrease in viscosity: a reduction factor of 4 to 10 should be applied to mantle-derived material if viscosity of mid-oceanic ridge basalts had to be used (Mei and Kohlstedt, 2000b). Laboratory experiments attempting to reproduce realistic thermal and mechanical conditions are however limited. As emphasized by Korenaga and Karato (2008), olivine rheology is complex since a minimum of eighteen parameters are required to write rheological laws. In addition, rheological laws for water-rich olivine suffer major uncertainties, as it is actually the case for crustal rocks (Burov, 2007). Recently, high-pressure and high-temperature experiments on deformation of dunite demonstrated that accounting for the role of oxygen fugacity in the range of upper mantle conditions, could decrease dunite viscosity by a factor of ~5 (Keefner et al., 2011). Korenaga and Karato (2008) illustrate different effective viscosity profiles for the upper 300 km of the mantle, for dry and wet cases and for different chosen geotherms; all viscosity profiles for
wet conditions show uncertainties of several orders of magnitude. The authors particularly insist on the large scatter of experimental data under wet conditions.

As far as thermal properties are concerned, it seems that they can be underestimated when experimental data are considered. Gibert et al (2005) concluded from their measurements that thermal diffusivity of mantle-derived material could be 50% higher than previously assumed. It follows that heat transfer processes related to low viscous olivine-rich rocks at high temperatures could thus be much more efficient, and thus much faster than commonly thought.

All the above-mentioned experimental data suggest that olivine-rich mantle rocks at high temperature may exhibit particular rheological behaviour involving strong strain and/or strain-rate softening mechanisms (see also Burov, 2011). As far as modelling parameters are concerned, density is here determined from mineralogical phases defined by ambient thermo-mechanical conditions (pressure and temperature) through equations of state derived for corresponding mineralogical compositions (see below). The effective viscosity is assessed from rock mechanics data on flow law parameters for given thermo-mechanical conditions, together with testing parameters of softening rules defining local strain-induced reduction in viscosity (see next section). Thus, the rheological model comprises distinct softening rules that are tested until a reasonable translithospheric diapirism mechanism is achieved.

4. Numerical model and preliminary tests

In the following, we present a series of numerical experiments aimed at reproducing the apparent “lithospheric diapirism” which is assumed to explain the ascent and emplacement mechanisms of Alaskan-type complexes. Main model features and tests experiments are first presented (Figure 3). Then, the results obtained with specific softening rules allowing the reproduction of typical geometries of Alaskan-type bodies are discussed.

4.1 Model features
We basically follow the philosophy of the earlier study by Gerya and Burg (2007), yet for a wider range of thermo-tectonic conditions, rheological assumptions and configurations specific to Alaskan-type complexes. We also test different softening rules and other parameters in order to assess the rheological properties of the lithosphere enabling for magma ascent from great depth. On the technical side, the main difference of our approach from that of the one developed in Gerya and Burg (2007) refers to a formally higher degree of physical consistency achieved through direct implementation of free surface, viscous-elastic-plastic rheology and phase changes (the two latter features were also integrated in the latest versions of the code by T. Gerya but were not applied to the problem of intrusion of ultramafic magmatic bodies). In particular, incorporation of continuous phase changes (Burov and Yamato, 2008) implies that rock density is thermo-dynamically consistent being dynamically updated as function of P-T (pressure and temperature) conditions from the equations of state $\rho = f(P, T)$ based on minimization of Gibbs free energy for given mineralogical composition. With that goal, the thermodynamic algorithm PERPLEX and its data base (Connolly, 2005) have been coupled with the main code. This approach not only provides more reliable values for density and for hence thermodynamically consistent definitions of thermal expansion $\alpha(P, T)$ and compressibility $\beta(P, T)$, but also for thermal and elastic parameters, the amount of released or absorbed fluids and other physical properties that can be used for thermo-mechanical calculations and on post-processing stage. As mentioned above, PERPLEX minimizes free Gibbs energy $G$ for a given chemical composition to calculate an equilibrium mineralogical assemblage for given P-T conditions:

$$G = \sum_{i=1}^{m} \mu_i N_i$$

(1)

where $\mu_i$ is the chemical potential and $N_i$ the moles number for each component $i$ constitutive of the assemblage. Given the mineralogical composition, the computation of density is then straightforward (e.g., Yamato et al., 2007; Burov and Yamato, 2008). Thermal expansion $\alpha_{\text{eff}}$ is corrected for latent heat following Gerya and Burg (2007):
\[ \alpha_{\text{eff}} = \alpha(P, T) + \rho_0 \frac{Q_l}{T} \left( \frac{\partial M}{\partial p} \right)_T \]  

(2)

where \( \rho_0, Q_l, M, T \) and \( p \) are density, latent heat of melt, volume fraction of melt, temperature and pressure, respectively. To solve the thermo-mechanical part of the problem, we use the code Flamar 12 (outgrowth of FLAC and Paravoz (Cundall, 1989; Poliakov et al., 1993)). Flamar is a well-tested code that has been used for many geodynamic applications including exhumation of metamorphic domes (Tirel et al., 2008), mantle-lithosphere interactions (d’Acremont et al., 2003; Burov and Cloetingh, 2009), continental collision (e.g., Toussaint et al., 2004; Burov and Yamato, 2008) and metamorphic rock exhumation (e.g., Burov et al., 2012). As its predecessors, Flamar is a large strain fully explicit time-marching algorithm that locally solves full Newtonian equations of motion in a continuum mechanics approximation:

\[ \langle \rho \dot{u} \rangle - \nabla \sigma - \rho g = 0 \]  

(3)

coupled with viscous-elastic-plastic constitutive equations (see Supplementary material):

\[ \frac{D\sigma}{Dt} = F(\sigma, u, \dot{u}, \nabla \dot{u}, \ldots) \]  

(4)

with equations of heat transfer and with state equations:

\[ \rho \ C_p \frac{DT}{Dt} - \nabla (k \nabla T) - H = 0 \]  

(5)

\[ \rho = f(P, T) \]  

(6)

Here \( u, \sigma, g, k \) are the respective terms for displacement, stress, acceleration due to body forces and thermal conductivity; dot represents the time-derivative; pressure \( P \) is negative for compression. In the eq. 5, heat advection term \( \dot{u} \nabla T \) is included in the Lagrangian derivative \( DT/Dt \). The triangular brackets in (3) specify conditional use of the related term as in quasi-static mode inertial terms are damped using inertial mass scaling (Cundall, 1989). The terms \( t, C_p, H \) designate respectively time, specific heat, and internal heat production (radiogenic heating, shear heating, latent heat). The expression \( \rho = f(P, T) \) refers to the density computed
by a thermodynamic module PERPLEX as function of $P$ and $T$. The terms $D\sigma/Dt$ and $F$ are the objective Jaumann stress time derivative and a functional, respectively. In the Lagrangian method, incremental displacements are added to the grid coordinates allowing the mesh to move and deform with the material. This allows for the solution of large-strain problems while using locally the small-strain formulation: on each time step the solution is obtained in local coordinates, which are then updated in a large strain mode.

Solution of (3) provides velocities at mesh points used for computation of element strains and of heat advection $\dot{u}V T$. These strains are used in (4) to calculate element stresses and equivalent forces used to compute velocities for the next time step. Due to the explicit approach, there are no convergence issues, which is rather common for implicit methods in case of non-linear rheologies. The algorithm automatically checks and adopts the internal time step using $0.1 - 0.5$ of Courant’s criterion of stability, which warrants stable solution.

4.2. Model setup and test experiments

We first run a series of experiments roughly following the strategy chosen by Gerya and Burg (2007), yet for conditions and parameters compatible with the Alaskan-type complexes. The setup of the models is following:

In the reference model, the computational domain is 1000 km wide and 300 km deep with a homogeneous grid comprising 600 x 260 rectangular elements. Some experiments were run using local mesh refinement allowing for higher spatial resolution in center of the model (0.8 km x 0.5 km). Depending on the experiment, the lithosphere was either 100 km or 200 km thick including 40 km thick crust. Semi-spherical 200 km (in some experiments 50 km or 100 km) wide magmatic source is placed at the bottom of the model. An initially narrow – 2 element wide – dike-like conduit connects the source region with the bottom of the crust (dashed white contour in Figure 3a). Density and viscosity contrasts impose large and fast modifications in the lithospheric and crustal stress regimes; thermo-mechanical evolution of the system is thus computed until high strain rates are achieved at the surface. Composition,
stress, strain and strain rates are computed for each grid cell, but “magma flow” (in terms of fluid dynamics) is not simulated in these experiments due to their time scales. The conduit is initially blocked at Moho depth to investigate further initialization of the potential magma pathways in the overlying crust. We do not continue experiments once the pathways are initialized since further propagation of magma and its interaction with the walls of the pathways are beyond the scope of this study, requiring a separate parametric investigation at local scale. The following illustrations show compositional fields and strain rate values that are computed after thousands years of evolution. In particular, large values of strain rates are assumed to be located where contrasts in physical properties are the highests. In other words, the terms “magma ascent” in the following text correspond to the upward migration of high strain rate zones.

In the reference experiments (Figure 3b and 3c) we have made a conventional assumption on the strength profile of the background lithosphere assuming initial geotherm yielding 60-70 mW/m² at surface (thermotectonic age of 100 Ma), granite-dominated crust, quartz-diorite lower crust and dry olivine mantle, and no ductile softening. We hence use olivine rheological parameters for mantle and quartz-granite rheology for the crust (see Supplementary material). The upper boundary condition is free surface, the bottom condition corresponds to Winkler basement (hydrostatic), and the lateral conditions are zero horizontal velocities. The thermal boundary conditions are zero temperature at surface, 1400°C at the bottom of the model (300 km depth), and zero lateral outflows. The phase changes are computed for the following compositions: mantle – peridotite; crust – granite; magma – partially molten peridotite.

4.2.1 The influence of compositional density contrast.

The density of partially molten magma is subject to large variations that depend on composition, transient $P$-$T$ conditions and fluid content. We thus first tested end-member cases with various density contrast cut-offs (as defined by $(\rho_m - \rho_b)/\rho_b$, where $\rho_m$ is magma density and $\rho_b$ the background rock density): from 0.1 to 0.5. In these experiments we did not
activate thermodynamic phase changes. These experiments show the extreme importance of the density contrast on magma emplacement and ascent rate (see Figure 3b, where density contrast between the magma and the mantle equals 0.4 and 0.2). It is important to note that magma ascent velocity is extremely high, reaching several tens to hundreds of m/yr. These values are in accordance with estimates from previous analytical and numerical studies that account for realistic (non-Newtonian) rheologies (e.g. Weingerg and Podladchikov, 1994; van Keken, 1997; Burov et al., 2003).

4.2.2 Experiments with thermodynamically consistent densities

The next series of reference experiments have been implemented with thermodynamically consistent account for phase changes (Figure 3c). Due to $P$-$T$ dependent density, surface impact of magma is moderate compared to the previous models with fixed density contrast; a relatively large secondary magma region forms at the base of the crust, sourcing magma propagation to the surface. One can observe, similarly to the experiments of Gerya and Burg (2007), that magma ascent creates a deviatoric stress field provoking brittle faulting at surface. The created faults go deep down to 40 km depth and thus may serve for channeling magma to the surface. It is noteworthy that formation of surface faults is conditioned by 2 major factors: (1) the assumed crustal geotherm and (2) magma viscosity cut-off. The background geotherm should be relatively cold in the crustal region to make brittle deformation possible while magma should not be neither too viscous nor too fluid: its viscosity must be lower than $10^{18}$ Pa.s, otherwise its ascent will be too slow and magma would be stalled at some depth, but greater than $10^{15}$ Pa.s, otherwise magma might spread laterally somewhere in the crust instead of pushing the brittle crust up. These high viscosity values are one order of magnitude higher than those used by Gerya and Burg (2007), where the associated melt fraction was around 10 to 30% vol. However, in case of the presence of external extensional field (tectonic extension), faults may be formed even in cases where the above conditions are not satisfied (see an example in Burov and Guillou-Frottier, 1999).
5. Experiments with softening mechanisms

As can be seen from the experiments of the previous sections, the reference thermo-rheological structure results in relatively weak ductile lower crust, so that magmatic material ascending from the chamber spreads laterally at some level within the ductile lower crustal layer resulting in distributed deformation at surface since it is denser than the normal crust. It follows that the magmatic conduit is destroyed in its crustal part.

For these reasons, further series of high resolution experiments tempted to find the rheological conditions under which the magmatic material can mechanically reach the uppermost crustal layers without destroying the integrity of the magmatic conduit. The major parameters that have been tested within these experiments were: (1) the lower crustal rheology; (2) mantle rheology and geotherm; (3) softening mechanisms in the brittle and ductile parts; (4) width of the magmatic conduit; (5) magma temperature.

Without detailing all experiments of this sensitivity study, we have found that preservation of the magmatic channel requires strong lower crustal rheology (“diabase/granulite”) and strong “aggressive” softening of the brittle and ductile material. We have also extended the brittle failure criterion by adding to the common Mohr-Coulomb criterion that operates under overall compression (i.e. negative pressure, \( P < 0 \)), the parabolic Griffith's criterion applicable in pure tension (positive pressure, \( P > 0 \)):

\[
\tau^2 = 4 T_0^2 + 4 T_0 \sigma_n
\]

where \( \tau \) is shear stress, \( T_0 \) is tension cut-off, typically 20-40 MPa, \( \sigma_n \) is normal stress. The Griffith failure can be controlled by varying \( T_0 \) (\( T_0 = 0 \) means permanent failure, \( T_0 = 1000 \) MPa means practically no tensile fracturing). As mentioned, this criterion applies when pressure becomes positive, in case of dilatation, basically in the uppermost rock layers (first kilometers in depth) where tensile stresses created by magma upraise and upward bending of the uppermost layers can negate lithostatic compressive pressure due to rock weight. Created tensile faults are “mode I” faults, i.e. these faults are normal to the tension axis while the Mohr-Coulomb faults are “mode II” faults. In deeper rocks total pressure is practically
always negative due to the rapidly growing weight of the rock column (about 25-30 MPa per km), so Mohr-Coulomb failure prevails.

The experiments detailed below show representative cases in which magmatic material arrives to break through the brittle crust and find its way to the surface. The series of experiments demonstrate the effects of different strain softening mechanisms in the ductile part. For the brittle part, we use linear cohesion softening, where cohesion drops from 20 MPa to 0 in the strain interval between 0.1 and 0.5. The used softening laws account for cumulative effects of grain size reduction, variations in fluid content in the deforming rock, partial melting and other effects mentioned in the previous sections. It is noteworthy that the choice of the form of the softening rule basically has no quantifiable experimental justification due to multiple processes involved. For example, Huismans and Beaumont (2003) assumed aggressive softening for the brittle and brittle rock assuming similar relations to show that the observed morphologies of rifted basins cannot be explained without frictional-plastic and viscous strain softening. Similarly, Gerya and Burg (2007) and most other workers assumed softening laws that basically do not stem from experimental rock mechanics but from field observations and thermo-mechanical models that show that at macroscopic scale faults and shear bands should undergo strong softening to explain the observed strain patterns and evolution of geological structures. In general, linear strain-softening laws (e.g., Huismans and Beaumont, 2003) are used and we here follow the same approach by implementing a simple piecewise linear ductile softening rule:

\[
\begin{align*}
\text{if } \varepsilon \leq \varepsilon_0, & \quad \mu(\varepsilon) = \mu(T,\sigma, \varepsilon', \ldots) \\
\text{if } \varepsilon_1 > \varepsilon > \varepsilon_0, & \quad \mu(\varepsilon) = \mu \left(1 - \lambda(\varepsilon-\varepsilon_0)/(\varepsilon_1-\varepsilon_0)\right) \\
\text{if } \varepsilon \geq \varepsilon_1, & \quad \mu(\varepsilon) = \mu \left(1 - \lambda\right)
\end{align*}
\] (8)

where \(\varepsilon_0\) and \(\varepsilon_1\) are respectively minimal and maximal accumulated strain values, within which progressive softening is applied; \(\mu\) is effective initial viscosity derived as function of \(T\), \(\sigma\), \(\varepsilon'\) and material parameters; \(\lambda\) is a constant viscosity factor such that \((1-\lambda)\) is maximal ratio between viscosity after and before softening, e.g., \(\lambda = 0.999900\) means 3 order maximal
reduction of viscosity. We changed $\varepsilon_0$ from 0.1 to 0.2, $\varepsilon_1$ from 0.5 to 2.0 and $\lambda$ from 0.90000 to 0.99999. Seven particularly remarkable cases are detailed below.

5.1 Case 1.

The experiment shown in Figure 4 corresponds to $\varepsilon_0 = 0.2$, $\varepsilon_1 = 0.5$, $\lambda = 0.99900$. This experiment clearly shows that the ascending magma has widened the initially thin channel (Figure 4a). Before arriving at the base of the crust, fractures – or weakness zones – developed at several locations, as it can be seen in the strain rate pattern of Figure 4b, which also shows localization of ductile strain near channel walls that are mechanically eroded during magma ascent. Note in Figure 4c that the surface uplift extends over a distance greater than 100 km, and that spacing between crustal channels of high strain rates equals, respectively, 42, 23, 10, 20, 15 and 15 km (av. 20 ± 10 km).

An additional peculiar feature is revealed in Figure 4b: some zones of high strain rate values in the crust (light green and yellow zones) exhibit a triangular configuration, or funnel-shape geometry. In addition, over the 8 fractured (weakness) zones, only one appears with an angle (laterally shifted body at shallow depths), the others being mostly vertical. Interestingly, 4 of them are not directly connected to the magmatic channel. These observations are consistent with several characteristics of the previously described Alaskan-type complexes, like the clustering phenomenon (see also discussion). Figure 4c illustrates the topography evolution, where fractures/channels are characterized by local subsidence, which is not visible at early stages. The large-scale doming begins to appear at ~0.5 kyr and clearly develops at later stages (after 2 kyr) while ascending magma has settled in the vertical conduits/channels and has sufficiently cooled.

5.2 Case 2.

These experiments (Figure 5) correspond to another softening mechanism, where controlling parameters are chosen as follows: $\varepsilon_0 = 0.1$, $\varepsilon_1 = 1.0$, $\lambda = 0.99900$. Reduction in viscosity is thus similar to the previous experiment, but the range of the accumulated strain values, for which progressive softening is applied, becomes larger. In other words, the upper
crust becomes weaker with time than in the previous experiment. It follows that the surface uplift observed before is smaller in these experiments, as can be seen from Figure 5. However, pattern of fracturation, which is actually determined by dynamics of ascending magma, remains relatively similar, consisting in regularly spaced channels of high strain rates (Figure 5). In that case, the funnel-shape structure is not observed, but two Y-shaped structures are present at both edges of the channel tip. These Y-shaped channels differ from conjugate fault zones in the crust, since they could be characterized by larger distance between two branches, by larger vertical size and potentially smaller width, and could also be called, in that case of Figure 5, “U-shaped” structures. It can also be mentioned that topography shows a slight subsidence at the top of each channel, resulting in an undulated surface topography over 100-150 km.

5.3 Case 3 and 4.

The experiments shown in Figures 6a and 6b correspond to another softening mechanism, where controlling parameters are chosen as follows: \( \varepsilon_0 = 0.2, \varepsilon_1 = 2.0, \lambda = 0.99999 \) (meaning that the reduction in viscosity reaches a factor of \( 10^5 \)). The range of strains where softening is applied is thus \( \sim \) twice wider than that in previous experiments. This results in a formation of a volcanic-like structure, where deep magma erupts at the surface. Figure 6a corresponds to a tension cut-off value of 10 MPa and Figure 6b shows the case of a tension cut-off value of 1000 MPa. Fractured zones can be inferred from step-like aspects of crustal layers.

5.4 Case 5.

In Figure 6c, controlling parameters are \( \varepsilon_0 = 0.2, \varepsilon_1 = 0.75, \lambda = 0.99900 \) and tension cut-off equals 1000 MPa (no Griffith’s criterion). Here again, fracture zones can be easily seen with step-like structures in crustal layers (see inset of Figure 6c). Magma reaches the upper crust and fracturing extends over \( \sim 100 \) km.

The three cases shown in Figure 6 do not illustrate Alaskan-type structures since at the lower crust level, the width of the magmatic channel has been enlarged up to 30-40 km. Contrarily to case 2 (shown in Figure 4) there is, for these 3 cases, no mechanical barrier
above which high strain rate zones would become distributed at the surface over 100-150 km. The following tests show additional Alaskan-type structures which were obtained while controlling parameters ($\varepsilon_0$, $\varepsilon_1$, $\lambda$ and $T_0$) were varied.

5.5 Case 6 and 7

Figure 7 shows two additional experiments where controlling parameters are respectively: $\varepsilon_0 = 0.2$, $\varepsilon_1 = 1.0$, $\lambda = 0.99900$, and $\varepsilon_0 = 0.1$, $\varepsilon_1 = 1.0$, $\lambda = 0.99990$. The first experiment (Figure 7a) shows seven Y-shapes structures, whose “trunks” are separated by 28, 55, 25, 23, 30 and 55 km (av. 36 ± 13 km). The second case (Figure 7b) shows seven cylindrical to funnel-shaped structures, separated by 25, 28, 10, 20, 30 and 32 km (av. 24 ± 7 km). As for cases 1 and 2 (Figures 4 and 5), a single deep magmatic source creates several weakness zones in the upper crust, separated by ~20-40 km, thus simulating the clustering aspect of magmatic channels (linear clusters shown in Figure 1).

Contrarily to cases 3, 4 and 5 (Figure 6), where deep material reaches the surface with no apparent mechanical barrier, the other results (Figures 4, 5 and 7) clearly shows at ~20 km depth some drastic changes in the mechanical regime, that favour lateral distribution of high strain rate values.

5.6 Individual bodies

In addition to the reproduction of clustered structures – at least in these 2D numerical models – the obtained geometries of individual weakness zones (or areas with high strain rate values) appear to replicate the schematic models inferred from geological studies, such as the laterally-shifted bodies suggested for Union Bay and Goodnews Bay complexes (Himmelberg and Loney, 1995; Van der Poel and Hinderman, 2000), or the Y-shaped body suggested by Thakurta et al. (2008) for the Duke Island complex. Figure 8 illustrates distinct numerical results of such individual geometries, where it can be seen that dimensions (largely exceeding the resolution limit) correspond to natural cases (see Table 1). Moreover, the amplitudes of the strain rate values (from light green to red delineated by black dashed lines) provide additional information: (1) the strain rate values tend to be higher in funnel-shaped and shallow Y-shaped structures; (2) these zones are located near the bottom parts
of inclined edges. When there are no inclined edges at shallow (~5-10 km) depths, i.e. for vertical pipes such as the two left ones of Y- (or more exactly U-) shaped structures (middle cases in Figure 8), strain rate values are rather homogeneous within the entire structure.

6. Alaskan-type complexes and their PGE mineralization

6.1 PGE concentration

PGE mineralization in Alaskan-type complexes is mainly associated with chromitites hosted by the dunite core. When compared to dunites, chromite concentrations appear to be significantly enriched in PGE by a factor of ~5-6 (Johan, 2002). As emphasized by many studies, mineralized chromitites from Alaskan-type complexes exhibit PGE concentrations anomalously enriched in iridium and platinum (Figure 9). Indeed, the available data (with few exceptions discussed hereafter) show a typical “M” pattern, the two peaks representing Ir and Pt concentrations (Garuti et al., 1997; Johan, 2002; Augé et al., 2005; Zacarini et al., 2011; Nazimova et al., 2011), whereas, by comparison, mineralized podiform chromitites from ophiolites show a decreasing trend from Os-Ir-Ru to Pt-Pd elements (e.g. Ahmed and Arai, 2002; Büchl et al., 2004; Zhou et al., 2005).

The PGE spidergram of Figure 9a illustrates this “M” pattern, as defined by typical mineralized chromitites from Alaskan-type bodies. Spidergram of Figure 9b gathers other data which can be considered as coming from anomalously mineralized chromitites (either an excess in Os or Pd, or an anomalously low signature in Pt). The Nizhny Tagil 3 and 4 samples correspond to chromitites of barren type and brecciated chromitites, respectively (Augé et al., 2005). Sample from the Butyrin vein in the Kytlym complex shows high concentrations of Os and Pd, while the two other samples (Kytlym 2 and 3) exhibit only slight anomalous Os concentrations and are thus not considered as anomalously mineralized. It is interesting to note that the distribution from the largest Alaskan-type body (the Guli massif, whose total area is around 2000 km², including two dunite cores covering 450 km²), exhibit the lowest Pt concentration with relatively high values for Os, Ir and Ru (Figure 9b). Malitch et al. (2002) also underlined that the common occurrence of Os-Ir-Ru alloys in chromitites
from the Guli massif matches with patterns obtained with ophiolitic massifs. This fact suggests that body size and mineralization features may be related. Another similar observation is described below.

Using geometrical classification described in section 2, the above PGE concentrations from typical mineralized chromites of Alaskan-type bodies (Figure 9a) have been separated in two groups defined by the number of dunite cores (Figure 9c and 9d). It turns out that single dunite cores (Figure 9c) show the lowest ranges of PGE concentrations (curves are located in the lower part of the M pattern area). Figure 9d gathers data from only twin Alaskan-type bodies, and include all the highest PGE concentrations. Note that data from the Uktus 2 sample, which may belong to Figures 9c or 9d (due to uncertainty in the initial number of dunite cores), do not alter this observation.

6.2 Inclined edges

Bottom parts of funnel-shaped ultramafic bodies (not necessarily of Alaskan-type) often correspond to mineralized areas (see discussion). Indeed, these high strain rate zones may concentrate magma pathways, thus enhancing potential for mineral deposition. These high strain rate zones (see section 5.6 and Figure 8), more frequent at the outer edges of the structure, may also explain the concentrically character of Alaskan-type complexes: in case of multiple magmatic pulses, the ascent of dunite cores would be easily followed by subsequent emplacement of pyroxenites around the dunite core, where high strain rate localized during the first ascent. Some field studies have shown a syn-emplacement deformation localized within the complex periphery (e.g. pyroxenite mylonites associated with dykes along borders of Svetloborsky complex, Urals, Tolstykh et al. (2011); solid-state deformation of the Galmoenan complex during ascent and emplacement, Burg et al., 2009). In addition, syn-emplacement deformation is compatible with a translithospheric mantle diapirism mechanism (Bodinier et al., 2002; Burg et al., 2009).

At a smaller scale, a detailed study of the Nizhny Tagil Complex shows that the Platinum Group Minerals (PGM) are systematically included in (or attached to) chromite crystals and are dominated by Ir alloys and Pt alloys, which explains the shape of the
spidergram in Figure 9a. There is a correlation between the PGE content of a given sample and its chromite content. A model has been proposed to explain this relationship, where early crystalized PGM (platinum-group minerals) will be trapped by chromite. The subsequent concentration and accumulation of chromite crystals will cause the PGE enrichment in chromitites. Study of morphology of chromite concentration in the Nizhny Tagil Complex permitted to propose a genetic model where chromite accumulates in cavities along magma conduit created within the dunite unit (Augé et al., 2005). In this model, the cavities created by physical processes were permanently fed by the magma going through the dunite body, the chromite being accumulated by convective processes (Augé et al, 2005, Fig. 14). Figure 10 illustrates this cavity model in the case of a Y-shaped Alaskan-type complex, with some field examples of different surface signatures of Alaskan-type complexes. It is here suggested that both high strain rate zones and the inclined edges of dunite cores of Alaskan-type complexes favour at a smaller scale magma pathways and thus mineralizing processes within cavities.

7. Discussion and conclusion

Alaskan-type bodies have been classified according to their geometrical features at the surface and to their supposed structure at depth. Clustering of several of such bodies within typical distance of tens to hundreds of kilometres represents a specific observation which was attempted to be reproduced through numerical experiments. Based on the emplacement mechanism defined by the ascent of hot magma from the base of the lithosphere through a dyke-like vertical conduit, numerical models have been performed to test the effect of different parameters (thermal regimes, conduit diameter, and rheological parameters) on the mechanical response of the upper crust. After a series of one hundred high resolution experiments, it appears that the only way to keep a vertical dyke-like conduit, while weakness zones develop in the upper crust, is to consider a strong lower crustal rheology and some particular softening mechanisms, including tensile failure and strong strain dependence, in the brittle and ductile domains.
Using ductile softening rules controlled by minimum and maximum accumulated strain values, a range of “Alaskan-type mechanical responses” have been obtained: (i) cluster of cylindrical and funnel-shaped structures, including laterally shifted bodies, separated by 10-40 km, with topographic uplift (Figure 6); (ii) cluster of cylindrical structures, separated by 10-30 km, possibly connected at depth, with pronounced surface subsidence (Figure 7); (iii) cluster of Y-shape structures, separated by 25-55 km, with no significant erosion/subsidence (Figure 7a), and (iv) cluster of funnel-shaped structures, separated by 10-32 km, with pronounced surface subsidence (Figure 7b).

Because of the restricted 2D numerical procedure, a detailed comparison of geometrical aspects of the clustering process is not feasible. In addition, the 2D Cartesian geometry involves a “dyke-like” conduit rather than a “pipe-like” conduit. Consequently, one could simply observe from our simulations that several separated weakness zones can develop within the upper crust over a distance of 100-150 km.

Besides reproducing individual or clustered weakness zones (Figures 4, 5 and 7), the results shown in Figure 8 raised an interesting question dealing with the apparent relationship between locations of high strain rate values and mineralization features reported in Figure 9. Indeed, supposed Y-shaped geological structures – or twin Alaskan-type bodies (Galmoenan, Goodnews Bay, Kachkanar, etc) show the highest PGE concentrations, and Y-shaped numerical bodies have the highest strain rate values. On the opposite, supposed cylindrical geological structures – or single Alaskan-type bodies (Konder, Nizhny Tagil, Tulameen, etc) have the lowest PGE concentrations, while cylindrical numerical bodies exhibit the lowest strain rate values.

Obviously, the lack of data on Alaskan-type intrusion prevents to go further in the interpretation of this relationship. Nevertheless, scarce examples of syntectonic funnel-shaped mafic/ultramafic intrusions exhibit similar geometrical relationships between both the location of melt injections and ore location (Ni–Cu ± PGE mineralization), and the high strain rate zones. For example, the Variscan Aguablanca gabbronorite intrusion (SW Iberia, Romeo et al., 2008) is a funnel-shaped mafic intrusion emplaced in a major shear zone. The Ni-Cu-
PGE mineralization is hosted by a funnel-like magmatic breccia located in the upper part of the funnel, close to the northern border of the intrusion. The mineralization is related to a final magmatic pulse injected within the shear zone (i.e. in the highest strain rate zone) controlling the mafic pluton emplacement. As a second example, the Permian Huangshandong ultramafic/mafic syntectonic intrusion (SW China, Branquet et al., 2012) is also a funnel-shaped intrusion with a sigmoid map shape emplaced within a major shear zone. Ni–Cu mineralization is located close to the border and to the bottom of the intrusion where several coeval melt injections (magmatic mingling) are located and controlled by the shear zone bounding the syntectonic intrusion. These analogies also suggest a control of high strain rate zones on successive magmatic injections and mineralization location.

The approach used in this study corresponds to a series of large-scale thermo-mechanical numerical models applied to metallogenic issues. It has been demonstrated by several authors that the investigation of magma emplacement mechanisms, and more generally of large-scale geodynamic processes, could bring new insights into the understanding of mineralization processes (e.g. Barley et al., 1998; de Boorder et al., 1998; Guillou-Frottier et al., 2000; Pirajno, 2004; Bierlin et al., 2006; Burov et al., 2007; Tosdal et al., 2009; Begg et al., 2010; Guillou-Frottier et al., 2012; Bertrand et al., 2014). Here, we have studied a peculiar magmatic process that involves thermal and mechanical processes at both large (mantle) and small (crust) scales. At these scales, rock properties spanned a wide range of temperatures and pressures, implying that particular caution had to be paid when rheological properties were assessed.

Since rheological parameters seem to control the way the upper crust is fractured, there is a priori no reason to assign a particular geodynamic context (e.g. subduction zone) to Alaskan-type bodies. This is consistent with the distinct geodynamic contexts where they occur (mainly in intra-continental and subduction-related settings). However, water-rich ultramafic magmas are probably more easily stored at the base of a continental lithosphere adjacent to a subduction zone.
The fast ascent of ultramafic magma through the lithosphere, which has been invoked by many authors (e.g. Beck et al., 2006; Chen et al., 2009) has been reproduced with a strong viscosity reduction due to strong strain softening. It can be underlined that our ascent velocity is ~50-100 times higher than in Gerya and Burg’s models (2007), whereas effective viscosities remain similar. The role of strain softening in viscosity reduction may thus be critical in the dynamical features of ultramafic magmatism.

Among the several unresolved issues which were presented in the introduction, we did not tackle directly the problem dealing with the restricted age range of Alaskan-type complexes. However, it was shown that the favourable rheological conditions required a strong lower crust rather than a weak and ductile lower crust. The possibility of a strong lower crust would thus exist on Earth for only ~500 Myrs, suggesting that a weak ductile crust was predominant prior to this time.

</tbody>
</table>
Highlights

- We numerically reproduced the geometries of Ural-Alaskan-type complexes
- Twin bodies correspond to horizontal cross-sections of Y-shaped structures
- Emplacement and clustering require strong lower crust and strong local softening
- High strain rate zones are located close to inclined edges of Y-shaped intrusions
- Chromite and PGE concentrations are related to geometry and high strain rate zones
