# 7 Abstract

8 The Ebro River in north-eastern Spain is among the largest contributors of freshwater to the 9 Mediterranean Sea and ends in the Ebro delta, one of the major wetlands in Europe. The bedrock of 10 the Ebro River basin mainly consists of carbonate rocks and evaporites of Paleozoic and Mesozoic 11 age, and the river flows through several large cities, and agricultural and industrial areas. The Ebro 12 River outlet at Amposta was sampled once a month for a year (2006), and a field campaign in April of 13 the same year sampled the Ebro along its main course as well as its principal tributaries. In the present 14 study, the behaviour of Li and its isotopes was investigated at basin scale, with the objective of 15 elucidating the processes controlling the isotope signatures of a large river draining mostly 16 sedimentary bedrock.  $\delta^7$ Li values ranged from +17.1% to +18.3% along the Ebro main stream, and 17 between +16.3 and +18.9‰ at the outlet. In the major tributaries, the  $\delta^7$ Li values ranged from +12.9‰ 18 to +20.9‰, with bedrock values ranging from +0.5 to +29.3‰. Comparing Li concentrations with Cl 19 and  $SO_4$  ones, it appears that evaporite weathering plays an important role in controlling Li, but no 20 anthropogenic agricultural or industrial influence on Li concentrations was detected. The Na/Li, Cl/Li 21 and SO<sub>4</sub>/Li ratios clearly reflect the role of halite dissolution for some tributaries (Gallego, Ega and 22 Aragon), gypsum dominating others (Guadalope, Matarrana, Huerva and Segre), and little influence of 23 carbonate in all tributaries, the Ebro itself being a mixture of all tributaries. We tentatively applied the 24 simple Rayleigh fractionation model, but most  $\delta^7 Li$  values of the Ebro water samples plotted away 25 from the fractionation line, reinforcing the major role of mixing processes in the Ebro basin, rather 26 than fractionation processes during water/rock interactions. A comparison of  $\delta^7$ Li values and  ${}^{87}$ Sr/ ${}^{86}$ Sr 27 ratios further demonstrates the role of gypsum/anhydrite and limestone in the Ebro and its tributaries. 28 Sr-isotopes show a non-negligible role of carbonate dissolution, generally considered to be weak in the 29 control of the lithium cycle in catchments.

31 Keywords: Ebro River, Li isotopes, dissolved load, evaporite, carbonate

# 32 **1 – Introduction**

33 Lithium is one of the modern tools for studying water-rock interaction processes. This is done 34 by coupling geochemical processes during such processes, with the capability of lithium to go 35 into the fluid phase with significant mass-dependent fractionation between the two stable 36 isotopes <sup>6</sup>Li (natural abundance 7.5%) and <sup>7</sup>Li (natural abundance 92.5%) (Huh et al., 1998, 37 2001; Pistiner and Henderson, 2003; Rudnick et al., 2004; Kisakürek et al., 2004; Pogge von Strandmann et al., 2006, 2014, 2021; Millot et al., 2007, 2010a, b; Négrel et al., 2012; 38 39 Dellinger et al., 2014; 2015; Henchiri et al., 2016; Négrel and Millot, 2019; Qi et al., 2019; 40 Martin et al., 2020; Steinhoefel et al., 2021; Millot and Négrel, 2021). Recently, the variation in  $\delta^7$ Li values of water was used for distinguishing between natural and anthropogenic inputs 41 42 because lithium isotopes have been shown to be a probe for tracing anthropogenic activity 43 (Choi et al., 2019; Négrel et al., 2010, 2019; Millot and Négrel, 2021).

44 Lithium and its isotopes are of increasing interest in weathering studies through rivers 45 dissolved and suspended loads and groundwaters because Li is solubilized from minerals and 46 rocks during water-rock interactions (e.g. a mobile element) and not constrained by biological 47 processes. Such chemical weathering induces isotopic fractionation resulting in an enrichment 48 of the heavy isotope (7Li) in solution, the light isotope (6Li) being preferentially retained in 49 secondary weathering mineral phases (see Négrel and Millot (2019) and references therein). 50 In systems where few secondary phases are formed, lithium can evolve in terms of a tool 51 tracing the mixtures between waters (see Négrel et al. (2010) and references therein).

The weathering of silicate rocks is a major process at the earth's surface and to better understand this process, many studies have deployed the use lithium isotopes(e.g., Burton and Vigier, 2011; Steinhoefel et al., 2021 and references therein). However, carbonate and evaporite weathering processes have hardly been studied through Li-isotope variations (Gou et al., 2019; Martin et al., 2020). This can be explained by two features: i) Li contents in 57 evaporite and carbonate are low ( $<12 \ \mu g \ g^{-1}$ ) compared to silicate rocks (20-40  $\mu g \ g^{-1}$  in 58 granite and around 60  $\mu g \ g^{-1}$  in shales); and ii) the most common rock types in Europe are 59 39% plutonic and metamorphic rocks, 37% shales, 14% carbonate rocks, 9.5% sand-60 sandstones, and volcanic rocks and evaporites playing a subordinate role (Caritat and 61 Reimann, 2012).

62 Here, we focus on Li-isotope data from the dissolved load of 25 river-water samples collected in the Ebro Basin and of 2 groundwater samples. Among the rivers providing 63 64 freshwater in the Mediteranean Sea, the 2017 Mediterranean Quality Status Report 65 (downloaded at https://www.medqsr.org/fr/node/230 on February 2023, 14th) classified the rivers having their outlet in the Mediterranean through their annual climatological discharge 66 67 of freshwater in cubic metres per second. The Rhone and Po rivers have the highest discharge  $(1500-1800 \text{ m}^3/\text{s})$ , then the Nile  $(1000-1500 \text{ m}^3/\text{s})$  followed by the Ebro and the Drin with 500-68 69 1000m<sup>3</sup>/s, reflecting the importance of the Ebro in the hydrologic cycle of the Mediterranean 70 Sea. The last rivers supplying the Mediterranean are the Ceyhan, the Evros and the Tiber 71  $(150-500 \text{ m}^3/\text{s})$  and the Moulouva and Shellif  $(10-150 \text{ m}^3/\text{s})$ . We measured lithium and its 72 isotope values in all reservoirs, in parts of the basin affected by salinization and secondary 73 processes (precipitation, re-dissolution, mixing of water and anthropization), as well as in the 74 main bedrocks. Studies on river drainage basin having evaporite-type bedrocks are scarce and 75 in these cases, the evaporitic deposits are often located in headwaters and are not very 76 important in terms of surface area compared to the general geology (mainly silicate rocks) and 77 to the size of these of large river basins. The  $\delta^7$ Li values generally observed in rivers draining 78 evaporites are either around +20 ‰ (Huh et al., 1998; 2001; Gou et al., 2019; Yoon, 2010) but 79 other rivers also influenced by evaporite dissolution have low  $\delta^7$ Li values, around +8% (Chen et al., 2002; Chetelat et al., 2008, 2009; Wang et al., 2015; Ma et al., 2020), whereas 80 carbonate-dominated rivers are characterized by high  $\delta^7$ Li values (> +20‰). The objectives 81

of our study were to constrain the Li cycling in a major river basin underlain by sedimentary rock and affected by climatic impact (drought and water deficit), and to examine Li in the rock-soil cycle through weathering processes and water use (agriculture, water reservoirs and industry), again within a climate-change context.

# 86 **2 - Characteristics of the Ebro Basin**

The Ebro River basin (Fig. 1) lies in north-eastern Spain, starting near the Atlantic coast in the Cantabrian Mountains and flowing to the western Mediterranean Sea. Over its 85,530 km<sup>2</sup> drainage basin and along its 928-km course, the Ebro River flows through several large cities (Lleida, Logroño, Vitoria, Zaragoza, Huesca and Barcelona), and through agricultural, mining and industrial areas. It is the largest Spanish river system and one of the largest contributors of freshwater to the Mediterranean Sea (CHE, http://www.chebro.es/).

93 The geology of the Ebro Basin consists of (Guillén and Palanques, 1992; Luzón et al., 94 2008; Mochales et al., 2007) sedimentary and metamorphic Palaeozoic rocks (Iberian and 95 Pyrenees mountains, Priorat Massif); Jurassic and Cretaceous carbonate rocks in the Iberian 96 Chain forming the southern margin of the Ebro Basin; sedimentary Tertiary rocks of the 97 Pyrenees foothills and the Ebro Valley; and Neogene and Recent delta-plain deposits near the 98 Mediterranean Sea (lower part of the Ebro River). The occurrence of evaporite deposits in the 99 Ebro River basin has been documented in detail (Castillo Herrador, 1974; Birnbaum, 1976; 100 Ortì, 1990; Utrilla et al., 1992; Elorza and Santolalla, 1998).

101 The main tributaries of the Ebro are the Aragon, Gallego, Cinca and Segre rivers 102 (northern part of the basin, Fig. 1) flowing through silicate rocks of the Pyrenees Mountains in 103 their upper part, and through sedimentary rocks downstream. In the southern part of the basin, 104 the main tributaries are the Huerva, Guadalope and Matarrana (Fig. 1), flowing over 105 sedimentary rocks. The catchment of the Ega River, a tributary in the upper part of the basin, 106 consists of sedimentary and metamorphic Palaeozoic and Mesozoic rocks of the Iberian 107 Chain. The four described climatic areas in the Ebro Basin (Batalla et al., 2004) are the 108 Atlantic headwaters (annual average precipitation about 900 mm and contribution to runoff 109 23%), the west-central Pyrenees (950 mm, 31%), the eastern Pyrenees (800 mm, 41%) and 110 the southern Mediterranean zone (500 mm, 5%), with a mean annual runoff of approximately 111  $6837.10^6 \text{ m}^3$ .

114	Figure 1. a- General location of the Ebro basin in Spain, location of sampling points in the Ebro
115	Basin. The main river was sampled upstream and downstream from the confluences of the main
116	tributaries, numbers 1 to 5 (number 5 being Tortosa); the tributaries were sampled at numbers 7 to
117	14. The Ebro outlet at Amposta (number 6; Cruzado et al., 2002) was sampled each month between
118	June 2005 and May 2006. Groundwater was also sampled at two locations in the Ebro Basin (number
119	15 Andosilla in Navarra; irrigation well at 6-m depth, and number 16 Lleida; irrigation well at 7-m

*depth*). Long-term evolution of the mean monthly discharge of the Ebro river in Tortosa (number 5,

modified from Négrel et al., 2007). b- Geological sketch map of ythe Ebor Basin, modified from Luzón
 et al., 2008 and Mochales et al., 2007).

123

The discharge of the Ebro River decreased from around 590 m<sup>3</sup> s<sup>-1</sup> in the "natural" 124 125 period 1914-1935, by 28% to 430 m<sup>3</sup> s<sup>-1</sup> in the period 1960-1990 because of increased water 126 use for irrigation, reservoir storage and electricity production, and domestic consumption 127 (CHE, 1996; Ibáñez et al., 1996). The main water use is for irrigation with almost 700,000 128 irrigated hectares (total water demand of 6310 Hm<sup>3</sup> y<sup>-1</sup>, CHE, 1996; INE, 2003), causing a 129 huge hydraulic deficit. Nearly 60% of the surface area of the Ebro River Basin is covered by 130 agricultural land, and around 50% of Spain's electricity is provided by hydroelectric power 131 plants along the Ebro system, causing another deficit. Around 14% of land use concerns urban 132 areas and industry, mainly located in the valleys.

More information on dissolved and suspended matter fluxes and weathering processes can be found in the different investigations we have conducted in the Ebro River catchment several, studying fluxes of (Négrel et al., 2007, 2016, 2021; Petelet-Giraud and Négrel, 2010).

136

# 3 – Material and methods

#### 137 3.1. Water and rock sampling

138 The Ebro River and its main tributaries were sampled in the centre of each river channel from 139 bridges (April 2006, Fig. 1). The main channel (samples 1 to 5, Fig. 1) was sampled upstream 140 and downstream from the confluences of the main tributaries (7 to 14, Fig. 1). In order to 141 monitor compositional variations over time in the river flow, the Ebro outlet at Amposta (6, 142 Fig. 1; Cruzado et al., 2002) was sampled each month between June 2005 and May 2006. To 143 provide an idea of the geochemical signature of potential groundwater input to surface water, 144 two groundwaters were also collected (15, Andosilla in Navarra; irrigation well G15 at 6-m 145 depth; and 16, Lleida; irrigation well GA-2 at 7-m depth). Representative gypsum, anhydrite 146 (4 samples) and carbonate (4 samples) bedrock samples were collected along the Ebro as well

147 (Fig. 1, A to H; Table 1), halite is from University collection.

#### 155 3.2 Methods

156 After collection, the water samples were filtered through pre-cleaned 0.45 µm acetate filters; 157 100 mL was acidified with double-distilled nitric acid to pH around 2 and stored in pre-158 cleaned polyethylene bottles for major-cation analyses, and a further 100 mL was stored 159 unacidified in polyethylene bottles for anion analysis. The water samples were analysed by 160 ion chromatography for major ions, and by ICP-AES for Ca, Na, K, Mg and ICP-MS for trace 161 elements (accuracy 5-10%) using protocols under accreditation. External and in-house 162 standards as well as reference materials was used to calibrate and validate the values. 163 Alkalinity was determined by the Gran titration method. We used HCl acid to titrate beyond 164 the equivalence point. The quantity of acid added to the pH around 3 is used to determine this 165 equivalence point with a mathematical method

Lithium-isotopic compositions (Millot et al., 2004) were measured with a Neptune Multi-Collector ICP-MS (Thermo Fisher Scientific). Chemical separation of lithium from the matrix before mass analysis used cationic resin (BioRad AG® 50 W-X12, 200–400 mesh)

169 and HCl acid (0.2 N) for 30 ng of lithium. Blanks for total chemical extraction were less than 20–30 pg Li, which is negligible as it represents a  $10^{-3}$  blank/sample ratio. The <sup>7</sup>Li/<sup>6</sup>Li ratios 170 were normalized to a  $\delta^7$ Li determination of about 0.1–0.2‰ (2 $\sigma$ m). Accuracy and 171 172 reproducibility of the total method (purification procedure + mass analysis) were tested by 173 repeated measurement of a seawater sample (IRMM BCR-403) after separation of lithium 174 from the matrix, for which we obtained a mean value of  $\delta^7 \text{Li}=+30.8\% \pm 0.4$  (2 $\sigma$ , n=15) over the duration of the analyses. This mean value agrees with our long-term measurements 175 176  $(\delta^7 \text{Li}=+31.0\% \pm 0.5, 2\sigma, n=30).$ 

# 177 **4 – Results**

Table 1 contains all analytical results for the different bedrocks and Table 2 contains data forthe river water and groundwater.

180

#### 181 4.1. Bedrock

The highest lithium content is observed in Trias-Keuper D anhydrite with a maximum around 11.3  $\mu$ g g<sup>-1</sup>, whereas the Oligocene B gypsum and Oligocene H carbonate have low lithium contents (about 1.4 to 1.7  $\mu$ g g<sup>-1</sup>). The  $\delta^7$ Li ranges from +0.5 to +0.9‰ for the lowest values, observed in Miocene A continental gypsum (Li content about 8.8  $\mu$ g g<sup>-1</sup>) and in Paleocene G continental carbonate (Li content about 3.7  $\mu$ g g<sup>-1</sup>), up to +29.5‰ in Trias-Keuper D anhydrite and a highest Li content of around 11.3  $\mu$ g g<sup>-1</sup>.

188 189

190

191

#### 193 4.2. Tributaries, Ebro main channel, and outlet survey

- 194 The eight sampled tributaries of the Ebro River (Fig. 1) show a minimum Li content of around
- 195 12  $\mu$ g l<sup>-1</sup> in the Rio Aragon and a maximum value of 66.9  $\mu$ g l<sup>-1</sup> in the Rio Guadalope. The
- 196  $\delta^7$ Li value ranges from +12.9‰ in Rio Matarrana to +20.9‰ in the Rio Cinca.

203

Similar to other studies of downstream and/or seasonal changes of lithium isotope ratios in river systems (Farber et al., 2004; Manaka et al. 2017; Pogge von Strandmann et al., 206 2017), we present their variation along the Ebro. Samples were collected from 100 km downstream of the river source to nearly the outlet, 450 km downstream.. The Li contents in tributaries, the main channel and the sampling-location distance from the source are plotted on Figure 2a, and the  $\delta^7$ Li values on Figure 2b.

The Li content in samples collected along the Ebro increases from  $5 \ \mu g \ L^{-1}$  farthest upstream, to  $23 \ \mu g \ L^{-1}$  350 km downstream, and then decreases to  $15 \ \mu g \ L^{-1}$  just before Amposta. During the survey in Amposta, Li contents varied between  $12 \ \mu g \ L^{-1}$  in May and  $36 \ \mu g \ L^{-1}$  in November. The  $\delta^7$ Li values along the main channel increased slightly from +17.1‰ in Miranda de Ebro up to +18.3‰ in Lodosa and then, until Tortosa, remained

223 invariant around +16.5‰ (Fig. 2b). At Amposta, the  $\delta^7$ Li value ranged between +16.3 and 224 +18.9‰. Please note the difference between the  $\delta^7$ Li values in Amposta and Tortosa (a few 225 km upstream), whereas Li contents remained similar. This agrees with the discrepancies noted 226 for the  $\delta^{44}$ Ca<sub>SW</sub> and Ca contents in the same sample set (Négrel et al., 2021). This difference 227 may be related to the fact that these isotopic systems are sensitive to fractionation processes 228 (Dellinger et al., 2015; Négrel et al., 2020; 2021), and to the presence of dams between 229 Tortosa and Amposta increasing fractionation (Gou et al., 2019), both factors influencing the 230 isotopic values. Concerning the dams, their physical role is the retention and release of water 231 stocks. Depending on the periods of filling and emptying, the water stocks have different ages as shown by Négrel et al., (2016) using H-O isotopes of the water molecule. These filling -232 233 emptying processes must affect the isotopic values of chemical elements like calcium and 234 lithium which are subject to fractionation processes.

235 The PHREEQ-C code (Parkhurst and Appelo, 1999) allows to calculate the distribution of aqueous species in water samples and the saturation index for minerals based 236 237 on the water data (e.g. the temperature, pH, redox and the concentrations of chemical 238 elements) and using the database of the thermodynamic parameters of the minerals (e.g. the 239 most recent Lawrence Livermore National Laboratory LLNL database). None of the water 240 samples in the Ebro Basin were undersaturated with respect to gypsum and anhydrite when 241 calculated with PHREEQ-C."Additionally, water samples of the tributaries and the Ebro were 242 systematically supersaturated for calcite, aragonite and dolomite. Samples from Amposta 243 showed various saturation degrees. Between December and May, the water samples were 244 undersaturated for calcite and dolomite (October to May for aragonite) and supersaturated 245 between June and November (or September for aragonite).

### 247 **5 – Discussion**

248

#### 249 5.1 Relative contribution to the dissolved Li load

It is generally agreed that dissolved Li in most of the world's major rivers comes from silicate weathering, and that the fraction derived from carbonate rocks or evaporite is negligible (e.g., Kisakűrek et al., 2005; Gou et al., 2019; Murphy et al., 2019; Martin et al., 2020). In addition, atmospheric deposition from cyclic salts plays a very minor role in the dissolved Li budget (Dellinger et al., 2015; Song et al., 2021). To overcome this input on the Ebro Basin, we corrected only for marine aerosols using the characteristics of modern seawater

256 The Li concentration from atmospheric input is given by multiplying the Cl 257 concentration from rainwater by the Li/Cl ratio in seawater (Négrel et al., 1993; Dellinger et al., 2015). With a maximum estimated chlorine concentration of 85  $\mu$ mol L<sup>-1</sup> deriving from 258 marine input (Avilla and Alarcon, 1999), and a seawater Li/Cl ratio of 5x10<sup>-5</sup> (Millot et al., 259 260 2010a), the calculated Li input from rain is low, with a maximum estimated contribution of 261 rainwater-derived Li in the Ebro Basin of 0.04-0.20% for the main tributaries, 0.10-0.40% for 262 the Ebro, and 0.09–0.20% for the outlet. In the Ebro Basin, due to its geological framework, 263 the contribution of carbonate and evaporite dissolution to the dissolved load should be the 264 major input, while the one from silicate can be ignored (Négrel et al., 2007; 2021; Petelet-265 Giraud and Négrel, 2010).

Figure 3 shows the binary plots between chemical elements in Ebro water, Li is compared to Cl (Fig. 3a) and SO<sub>4</sub> (Fig. 3b). The dissolved load of the Ebro basin (tributaries, main channel, outlet and groundwater) is clearly controlled by gypsum/anhydrite and halite dissolution; few or none of the samples are close to the seawater dilution line regardless of the concentrations (Ega and GA2 groundwater (16, Fig. 1). As can be seen in Figures 3, two main evolution trends explaining most of the Ebro Basin samples, namely the halite-dissolution and gypsum/anhydrite -evolution lines, respectively constrained by variations in Cl and in SO<sub>4</sub>
concentration.

274 In the Cl vs. Li plot (Fig. 3a), the gypsum/anhydrite -evolution line explains the 275 sample values in the Matarrana, Segre and Guadalope tributaries. The halite-dissolution line 276 explains the Aragon, Ega and Gallego tributaries, as well as the samples from the Ebro at 277 103 km and 241 km from the river source, several outlet results, and groundwater GA15. The 278 rest of the samples plot between these two trends. In the SO<sub>4</sub> vs. Li plot (Fig. 3b), the 279 gypsum/anhydrite -evolution line explains the Gallego, Huerva, Segre and Guadalope 280 tributaries, the Ebro sample at 103 km and 241 km from the river source, and groundwater 281 GA15. The halite-dissolution line explains the Matarrana, Ega, Aragon and Cinca tributaries, 282 the Ebro samples at 281 km, 336 km and 543 km from the source, and all samples from the 283 outlet surveys.

284

Figure 3. Data from the Ebro Basin regarding tributaries, main channel, outlet and groundwater for concentrations of (a) Cl vs. Li, and (b)  $SO_4$  vs. Li (all values in  $\mu g L^{-1}$ ).

The distribution along the two main evolution lines confirms that evaporite weathering
plays an important role in controlling Li concentrations, as shown for Cl–SO<sub>4</sub> (Négrel et al.,

291 2007; Petelet-Giraud and Négrel, 2010). This is in agreement with Isidoro and Aragüés, (2007) who argue that the salinity of water in the Ebro basin originates from three major 292 293 sources, associated with three minerals, namely gypsum/anhydrite, halite and calcite. 294 Regarding a possible anthropogenic control on Li concentrations, in addition to bedrock 295 sources of dissolved chloride-sulphate, the streams in the Ebro Basin are likely to integrate 296 input from farming and industrial activities. Pollutant investigations have revealed high 297 concentrations near industrial sites for persistent organic pollutants and heavy metal (Bovolo 298 et al., 2011). Among framing impacts, the main pressure on water quality in the Ebro basin is 299 from irrigated areas through the irrigation return flow. The different components of the 300 irrigation return flow are bypass waters, tail-waters and subsurface drainage waters that may 301 be enriched in phosphorous, pesticides, salts and agrochemicals (Aragües and Tanji, 2003) 302 and constitute generally the primary source of pollution. Heavy metal, pesticide and nutrient 303 pollution are widespread in relation to farming activities (pesticides and fertilizers 304 uses).Nitrates fluctuate little, between 4 mg L<sup>-1</sup> (Gallego) and 19 mg L<sup>-1</sup> (Huerva) for the 305 maximum range observed in tributaries. Regarding the Ebro itself, the highest NO<sub>3</sub> value  $(16 \text{ mg L}^{-1})$  is observed at 281 km from the river source, decreasing to 9 mg L<sup>-1</sup> at 543 km 306 307 from the source. All outlet survey samples agree with this range of values (6 to 14 mg L<sup>-1</sup>). 308 No relation is observed between NO<sub>3</sub> and Li concentrations and NO<sub>3</sub> and Cl concentrations, 309 except that the highest NO<sub>3</sub> values correspond to the lowest Li ones. This shows the unrelated 310 behaviour of these elements and the fact that no anthropogenic agricultural or industrial 311 influence on Li can be detected in the Ebro Basin. Even in the two groundwater samples, the high NO<sub>3</sub> concentrations (GA2 = 56 mg L<sup>-1</sup>, GA15 = 88 mg L<sup>-1</sup>) are not mirrored by high Li 312 313 contents, confirming the different origins of Li and NO<sub>3</sub>, with a major lithological control for 314 Li.

317 It is now well agreed that  $\delta^7 Li$  values in river waters are higher than in the parent rocks, due to 318 the strong fractionation between the <sup>7</sup>Li and <sup>6</sup>Li isotopes during weathering (e.g., Huh et al., 319 1998; 2001; Pistiner and Henderson, 2003; Kisakurek et al., 2005; Vigier et al., 2008; Millot 320 et al., 2010a; Verney-Carron et al., 2011, Dellinger et al., 2015; Wang et al., 2015; Bagard et 321 al., 2015; Négrel and Millot, 2019; Gou et al., 2019; Steinhoefel et al., 2021). While the <sup>6</sup>Li 322 isotope is preferentially retained and incorporated into secondary weathering products such as clays and oxides, the <sup>7</sup>Li isotope is enriched in the dissolved load, leading to relatively high 323 324  $\delta^7$ Li values in rivers.

The  $\delta^7$ Li values are commonly correlated with the Na/Li ratio (Millot et al., 2010; Dellinger et al., 2015; Wang et al., 2015; Négrel et al., 2020) and less with the Cl/Li and SO<sub>4</sub>/Li ratios (Liu et al., 2011). Figure 4 plots Na/Li ratios *versus* Cl/Li (4a) and SO<sub>4</sub>/Li (4b) ones and, in addition to the halite and gypsum/anhydrite dissolution end-member, we consider here Parker's (1967) carbonate dissolution end-member.

- 331

333

334335

Figure 4. Data from the Ebro Basin concerning tributaries, main channel, outlet and groundwater for concentrations of: (a) Na/Li vs. Cl/Li ratios (in mol/mol), (b) Na/Li vs. SO<sub>4</sub>/Li ratios (in mol/mol).

336

337 Na/Li versus Cl/Li ratios (Fig. 4a) show the role of halite and gypsum/anhydrite psum 338 dissolution, but less that of carbonate. All samples plot along a linear trend with increasing 339 Na/Li and Cl/Li ratios. More precisely than the relationships shown on Figure 3, because 340 concentration effects are reduced when using element ratios, it appears that the Guadalope, 341 Matarrana, Huerva and Segre tributary samples agree with gypsum/anhydrite dissolution, 342 whereas the Gallego, Ega and Aragon ones and GA2 (groundwater) reflect the dissolution of 343 halites. The Ebro samples at 103.5 km from the source appear shifted to the right due to 344 carbonate dissolution, but some samples from the outlet surveys (August to November) are 345 more influenced by halite dissolution when compared to the rest of the survey. The Na/Li 346 versus SO<sub>4</sub>/Li ratios (Fig. 4b) reflect a more complex behaviour. Guadalope, Matarrana, 347 Huerva and Segre still agree with gypsum/anhydrite dissolution, but Aragon and Cinca for the 348 tributaries, and samples from the Ebro and the outlet show a lowering of SO<sub>4</sub>/Li ratios 349 through carbonate dissolution. Gallego and Ega tributary samples and the August to 350 November ones for the outlet are also affected by halite dissolution. Na and Li thus seem to 351 be good indicators of rock-weathering processes in the Ebro Basin, combined as either Na/Li 352 or Li/Na ratios.

It is generally accepted that a positive relationship between the Na/Li molar ratio and the  $\delta^7$ Li value relates to silicate weathering (Millot et al., 2010; Liu et al., 2011; Dellinger et al., 2015; Wang et al., 2015; Négrel et al., 2020; Steinhoefel et al., 2021), whereas no relationship exists when water is strongly affected by evaporite dissolution (Liu et al., 2011; Wang et al., 2015). In the case of water-evaporite interaction, the Na/Li molar ratio can fluctuate strongly (200 to 550 on the Qinghai-Tibet Plateau; Liu et al., 2011), but less than the variation observed in the Ebro Basin (400 to 3800; Fig. 5a).

362

360

361

Figure 5. (a) Relationship between dissolved δ<sup>7</sup>Li values and molar Na/Li ratios in samples
from the Ebro Basin (tributaries, mainstream, outlet, groundwater) and from bedrock.
(b) Relationship between dissolved δ<sup>7</sup>Li values and molar Li/Na ratios with the simple
Rayleigh fractionation model (dotted lines).

Referring to Figure 5, the Segre, Huerva, Matarrana and Guadalope samples are 368 369 influenced by gypsum/anhydrite dissolution, whereas the Aragon, Gallego and Ega ones show 370 halite-dissolution influence. Thus (Fig. 5a), as these two groups of rivers constitute the 371 extremes of the Na/Li molar-ratio values, the main influence on this ratio is that of the nature of the weathered rocks rather than a fractionation effect (see below). The main feature of 372 373 Figure 5a is the evidence of two end-members in the tributaries, one marked by 374 gypsum/anhydrite dissolution with low Na/Li molar ratios and the other one marked by halite 375 dissolution with a higher Na/Li molar ratio. Both end-members help explaining the variations 376 observed in the Ebro itself and at the outlet, even if the variations are more marked for the 377 Na/Li molar ratios rather than on the  $\delta^7$ Li values (Fig. 2a). This scheme reflects a mixing for Li and its isotopes in water being mainly affected by evaporite dissolution, even if the role of 378 379 carbonate dissolution (less marked in Na concentrations) and a possible influence of Li380 isotope fractionation cannot be precluded. The samples collected along the Ebro itself evolve along this mixing scheme. The most upstream value corresponds to an end-member 381 382 characterized by halite dissolution, and farther downstream the samples are increasingly marked by a component defined by gypsum/anhydrite dissolution. Most of the samples 383 384 collected at the Ebro outlet can be explained by a component characterized by 385 gypsum/anhydrite dissolution, except for the samples from August to December, with a 386 higher influence of the end-member defined by halite dissolution. Using O and H isotopes, 387 Négrel et al. (2016) showed that from September to November, the Ebro at the outlet is 388 mostly supplied by groundwater and some water retained by dams, as the main river discharge 389 is low. This causes a data shift towards the halite-dissolution end-member, which is well 390 reflected in the groundwater sample that exceeds the Na/Li molar ratio in the Gallego and 391 Cinca waters, reflecting a large influence of evaporite dissolution. This can be due to a double 392 influence of mainly halite dissolution and, secondarily, gypsum/anhydrite dissolution (Figs 2a 393 and 2b) for the E16 groundwater sample from a 7-m-deep irrigation well in Lleida (16, 394 Fig. 1).

In order to complete this interpretation, we tentatively applied the simple Rayleigh fractionation model (Fig. 5b) that can describe Li removal from water to secondary phases, using the Li/Na molar ratio and the  $\delta^7$ Li values (Bagard et al., 2015; Manaka et al., 2017). This model is described by the general equations:

- 399  $\delta^7 Li_w = \delta^7 Li_i + 1000(\alpha 1) \ln(f^{Li}_w)$  (Eq. 1)
- 400

$$f^{Li}_{w} = Li/Na_{w}/Li/Na_{i}$$
 (Eq. 2)

401 where  $\delta^7 \text{Li}_w$  and  $\delta^7 \text{Li}_i$  are the Li isotope composition of the dissolved phase w and its initial 402 value in the rocks i,  $\alpha$  is the fractionation factor, and  $f^{\text{Li}}_w$  is the Li fraction remaining in the 403 dissolved phase. 404 However, such a model requires an initial value for calculating the fractionation effect 405 on the Li isotopes. Due to the congruent dissolution of evaporite deposits, we applied Eq. 1 on 406 two initial values representative of the extreme rock end-members, and then examined the 407 Rayleigh fractionation curves obtained by applying Eqs. 1 and 2. These end-members are the 408 two gypsum samples, one from Miocene continental deposits (A in Table 12) with a  $\delta^7 Li_i$  of 409 0.49 and Li/Nai of 0.29, and the other from Oligocene continental deposits (B in Table 1) with 410 a  $\delta^7$ Li<sub>i</sub> of 4.11 and Li/Na<sub>i</sub> of 0.0091. Values generally used for the fractionation factor  $\alpha$  range 411 from 0.996 to 0.993 (Bagard et al., 2015; Manaka et al., 2017)-the latter being accepted for 412 the Ganges, and down to 0.991 for the Amazon River (Dellinger et al., 2015). This range of 413 the fractionation factor  $\alpha$  is generally used for silicate weathering studies (Golla et al., 2021), 414 or for large watersheds of varied geology, such as the Ganges or Amazon Basins (Dellinger et 415 al., 2015; Pogge von Strandmann et al., 2021; Yoshimura et al., 2021).

416 Figure 5b illustrates the relationship between dissolved  $\delta^7$ Li values and molar Li/Na 417 ratios, with the simple Rayleigh fractionation model from Eqs. 1 and 2. Guadalope plots 418 within the fractionation lines, but Mattarana and Huerva (and Segre to a lesser extent) plot 419 along fractionation line starting from sample B (Oligocene continental deposits). However, 420 most of the  $\delta^7$ Li values of the water samples in the Ebro plotted away from the fractionation 421 line for  $\alpha$ =0.992 chosen on Fig. 5b. This value of 0.992 is close to the  $\alpha$  calcite-solution given 422 by Day et al. (2021). It therefore seems confirmed that the Rayleigh fractionation model, as 423 described in Equation 1 and shown on Figure 5b, is not valid in the case of the Ebro. This may 424 be explained by three points. The first concerns the non-removal of Li from water to 425 secondary phases caused by the presence of many dams on the river and its tributaries that 426 trap the suspended load, which is reduced to a few mg/L at Amposta (Négrel et al., 2007) 427 precluding this process. The second explanation concerns the impossibility of applying a 428 fractionation model in this particular case, which may be due to the fact that i) the model was 429 generally applied in rivers draining silicates (Kisakurek et al., 2005; Millot et al., 2010a; 430 Dellinger et al., 2014; 2015), and that ii) the derived  $\alpha$  values were defined under specific 431 weathering conditions or in laboratory experiments, but not under evaporite and carbonate 432 weathering (Song et al;, 2021). The third explanation concerns another process that can 433 control Li at the Ebro Basin scale: in the limestone-evaporite dominated rivers from the Ebro 434 Basin, we have modelled the Sr isotopes as a mixture between carbonate and evaporite 435 endmembers that cover the variability of all samples from the Ebro Basin (Négrel et al., 436 2021). This reinforces the major role of mixing processes in the Ebro Basin rather than 437 fractionation processes, previously reported and discussed for silicate rocks.

438

#### 439 5.3 Coupling Li and Sr isotopes: lithological control and mixing processes

440 Several studies (Phan et al., 2016; Manaka et al., 2017) have shown that  $\delta^7$ Li combined with <sup>87</sup>Sr/<sup>86</sup>Sr isotopes has the potential of distinguishing between the different rock types subject 441 442 to weathering, or of explaining mixing processes (Henrichi et al., 2016; Li et al., 2020). Sr 443 isotopes are a robust tracer of mixing because these isotopes do not fractionate (Millot et al., 444 2011) and combine with Li when the effects of weathering (and/or mixing) supplant those of 445 the fractionation between water and secondary phases (Schmitt et al., 2012). Figure 6a illustrates the relationship between  $\delta^7$ Li values and  ${}^{87}$ Sr/ ${}^{86}$ Sr ratios in the dissolved load from 446 447 the Ebro Basin and the various carbonate and evaporite bedrocks. We first note that the Li and 448 Sr isotopes are scattered in the different bedrocks, whose three apexes are the carbonates G 449 (continental Paleocene) and H (Oligocene carbonate), and the evaporite D (Trias anhydrite). 450 Furthermore, all water samples collected in the Ebro Basin lie within the area defined by the 451 bedrocks and define a positive trend (grey arrow on Fig. 6a). Negrel et al. (2021) found that 452 the Sr-isotope levels in the Aragon, Ega, Matarrana and Guadalope samples are explained by 453 a mixing scheme that is mainly influenced by evaporite weathering (gypsum/anhydrite and

halite), whereas the Huerva, Gallego, Cinca and Segre samples show a shared role ofevaporite (halites) and carbonate weathering.

456

457

458

459 Figure 6. a - Relationship between dissolved δ<sup>7</sup>Li values and <sup>87</sup>Sr/<sup>86</sup>Sr ratios in the samples
 460 from the Ebro Basin (tributaries, mainstream, outlet, groundwater) and bedrock (A to H,
 461 Table 1).
 462 b - Extended view of the relationship between the δ<sup>7</sup>Li values and <sup>87</sup>Sr/<sup>86</sup>Sr ratios in the Ebro

463 basin samples. The carbonate end-member is from Négrel et al., 2021 and this study). Solid
 464 lines show theoretical mixtures between the different end-members.

465

The relationships between several end-members in Figure 6a are represented by hyperbolae (Langmuir et al., 1978; Négrel et al., 2010) and can be expressed as by equation 3, below, I<sub>mix</sub> being the isotope composition of the mixed solution:

469

 $I_{mix} = \{([]_a x I_a x m)/([]_{mix})\} + \{([]_b x I_b x (1-m))/[]_{mix}\} (Eq. 3)$ 

470 where []<sub>a</sub>, []<sub>b</sub> and []<sub>mix</sub> are the Li or Sr concentrations for the solution mix from two end-

471 members a and b, I<sub>a</sub>, I<sub>b</sub> and I<sub>mix</sub> are the Li or Sr isotope compositions or value for the solution

472 mix from two end-members a and b, and m is the mixing proportion.

Figure 6b shows the relationships between the  $\delta^7$ Li values and the  ${}^{87}$ Sr/ ${}^{86}$ Sr ratios, and the mixtures between different end-members are represented by curves according to Eq. 3. 475 Considering only mixing processes, all samples are explained by mixing lines with different 476 end-members, here represented by the Matarrana and Guadalope samples for the 477 gypsum/anhydrite dissolution end-member, and by the Cinca and Gallego ones for the halite 478 dissolution end-member (Figs. 4 and 5). Négrel et al. (2021) found that the Segre water is 479 strongly influenced by carbonate dissolution, and was therefore selected to represent this end-480 member. Mixtures between Matarrana-plus-Segre and Guadalope-plus-Cinca (and a mixture 481 between Matarrana and Cinca) explain all Li-Sr relationships in the Ebro Basin samples. This 482 mixing scheme again illustrates the major role of evaporite dissolution on Li isotopes, with a 483 non-negligible role of carbonate dissolution, generally considered to be weak in controlling 484 the lithium cycle in watersheds (Kisakurek et al., 2005; Wang et al., 2015).

485

### 486 **6 – Conclusions**

487

The Ebro River Basin is the largest catchment of the Iberian Peninsula and one of the largest in the Mediterranean region. Investigations of surface waters and groundwaters defined a detailed behaviour of Li isotopes in the weathering environment at catchment scale. In the rivers dominated by limestone-evaporite bedrock, the waters are isotopically in accordance with the bedrock for their  $\delta^7$ Li signatures.

493 Li, Cl and SO<sub>4</sub> concentrations show that they are controlled by evaporite weathering, 494 and that a possible anthropogenic agricultural or industrial influence on Li concentrations can 495 be discarded. The Na/Li,  $\delta^7$ Li, Cl/Li and SO<sub>4</sub>/Li ratios reflect the role of halite dissolution for 496 some tributaries, gypsum/anhydrite dissolution dominates others, but the role of carbonate 497 weathering is minor. Samples from the Ebro main channel and from the outlet logically 498 showed a mix of waters. 499 Application of the Rayleigh fractionation model cannot explain the observed data. This 500 fact reinforces the major role of mixing processes in the Ebro Basin as fractionation cannot 501 explain the mineral concentrations in most samples. The mixing model is further confirmed 502 by comparison of  $\delta^7$ Li values and  ${}^{87}$ Sr/ ${}^{86}$ Sr ratios.

503 Compared with results from other large basins, such as the Amazon, Congo and 504 Ganges-Brahmaputra ones, as well as with data from much smaller catchments and even soil 505 profiles, our study confirms that lithium isotopes are a powerful tool for tracing basin 506 evolution, through different weathering regimes, relief and climate conditions observed in 507 various bedrock-types catchments, including carbonate-evaporite-dominated catchments.
